A Contrastive-Pairs Benchmark for Structural Manipulation

Protocol and Pilot — Does a Model Detect Rhetorical Structure, or Only Vocabulary?

Working note · Version 0.1 (pilot) · November 2026

1. Why this benchmark exists

The working papers in this programme established that a contextual model classifies PropXplain's propaganda labels better than a lexical one. Independent audits raised the deeper question those papers could not answer: does any of these models detect manipulation as a structure, or do they merely key on vocabulary? A model that flags “propaganda” because the text contains charged words has learned a lexical correlate, not the rhetorical mechanism. This benchmark is built to separate the two.

The method is contrastive pairs. Each item is a pair of short texts on the same topic, using as nearly as possible the same words, where one member carries a manipulative rhetorical structure — a presupposition, a manufactured equivalence, a false dilemma, a whataboutist deflection, a loaded rhetorical question, an implied causation — and the other states the same content plainly, without that structure. Because the vocabulary is matched, a model that scores the manipulative member higher must be responding to something beyond the words. The primary metric is pair accuracy: the fraction of pairs in which the manipulative member receives the higher propaganda score. A purely lexical model, on perfectly matched pairs, should sit near 0.5; a model sensitive to structure should sit well above it.

2. What the benchmark measures, and what it does not

This benchmark measures sensitivity to rhetorical structure, holding vocabulary approximately fixed. It does not measure whether a text “is propaganda” in any political or legal sense, whether it would persuade a real audience, or whether the construct “manipulation” is validly operationalized at all. It is one instrument in a construct-validity programme, not a verdict. A high pair accuracy is evidence that a model represents structure; it is not evidence that the model, or the corpus labels it was trained on, captures manipulation as it operates in the world. The ethical boundary of the wider programme applies here too: an instrument that scores rhetorical structure must never be used to adjudicate which political positions are legitimate.

3. Construction rules for a pair

A valid pair satisfies five rules. First, same topic: both members concern the same event, actor, or policy. Second, matched vocabulary: the two members should share as many content words as possible; the structural difference, not the word list, should distinguish them. Third, one structural device: the manipulative member introduces exactly one named technique, so that a failure can be attributed. Fourth, a plain control: the control states the same content as an open, attributed, or multi-option claim, removing the device without adding a new one. Fifth, a written rationale: each pair records, in one sentence, why the manipulative member is manipulative and why the control is not.

Pairs are labelled by technique so that pair accuracy can be reported per technique, which is where the interesting structure lives.

4. Metrics and controls

The headline metric is pair accuracy with a binomial confidence interval. Two controls guard against misreading it. The first is a lexical-overlap control: for each pair we report the Jaccard overlap of the two members' word sets. If overlap is low, the pair is poorly matched and a lexical model can win on vocabulary alone, so pair accuracy on low-overlap pairs is not clean evidence of structure sensitivity; the benchmark should report accuracy conditional on overlap, or restrict to high-overlap pairs. The second is the baseline-versus-contextual comparison: the key quantity is not either model's absolute pair accuracy but the margin by which a contextual model exceeds the lexical baseline on well-matched pairs. That margin, if positive and robust, is the evidence that context buys structural sensitivity — the claim the corpus studies could not establish.

5. Pilot results (Version 0.1)

A 24-pair pilot was written across six techniques (presupposition, manufactured equivalence, false dilemma, whataboutism, loaded rhetorical question, implied causation), four pairs each. Scored with the TF-IDF + logistic-regression baseline trained on PropXplain, the pilot gives the results in Table 1.

Technique	Pairs	Baseline pair acc.	(correct)
presupposition	4	0.75	3/4
manufactured equivalence	4	1.00	4/4
false dilemma	4	0.25	1/4
whataboutism	4	0.50	2/4
loaded rhetorical question	4	0.75	3/4
implied causation	4	0.75	3/4
ALL	24	0.667 [~0.48, 0.86]	16/24

Table 1. Lexical baseline on the 24-pair pilot. Mean lexical Jaccard overlap between members was 0.21 — modest, so these pilot pairs are not yet tightly matched.

The pilot is a proof of method, not a result to lean on, and it is honest about its own weakness. The mean lexical overlap of 0.21 is low: the manipulative members still carry distinctive charged words (for example in manufactured-equivalence pairs, which the baseline got 4/4 — almost certainly by keying on words like “dictatorships” or “arsonist” rather than on the equivalence structure). The baseline’s 0.667 overall is therefore inflated by vocabulary, not a measure of structural sensitivity. The lesson is the central design lesson of the whole benchmark: writing pairs that are genuinely matched on vocabulary is the hard, expert part, and it is exactly the contribution a scholar of manipulation is positioned to make. Version 0.2 should raise lexical overlap substantially and report accuracy only on high-overlap pairs.

6. The experiment this sets up

Once the pairs are tightly matched, the decisive comparison is between the lexical baseline and the contextual transformer on the same pairs. If the transformer’s pair accuracy exceeds the baseline’s on

high-overlap pairs — that is, when vocabulary cannot explain the difference — that margin is the first direct evidence that context captures rhetorical structure, not just words, which is the claim the corpus-level studies in this programme could not establish. The script 06_transformer_pairs.py produces the transformer's per-member scores; evaluate_pairs.py computes pair accuracy for either model. The benchmark then extends naturally: more techniques, more pairs per technique, independent human annotation of the pairs (so the labels are not the author's alone), and stronger models.

7. Next steps

In order: raise lexical overlap and re-score the baseline, restricting to well-matched pairs; run the transformer on the pairs and report the baseline-to-transformer margin; obtain at least one independent annotator's judgments on the pairs and report agreement; expand to roughly ten pairs per technique; and only then write this up as a short paper. Construct validity is earned pair by pair, not claimed. The materials — pilot pairs, scoring harness, and this protocol — are in the repository so that others can inspect, criticize, and extend them.

Materials

Pilot pairs, the evaluation harness (evaluate_pairs.py), the transformer scorer (06_transformer_pairs.py), and this protocol are maintained at github.com/politomorphism/politomorphism-defense.
